I. INTRODUCTION

The original Bardeen-Cooper-Schrieffer (BCS) theory is well known to be based on the assumption of spatially isotropic (s-wave) spin-singlet Cooper pairing. However, this kind of pairing is not unique, and a variety of superconducting (many kinds of metallic conductors) or superfluid (He) order parameters of other types are possible, in principle. As for high-$T_c$ superconducting cuprates, the majority of researches believe on the possibility, in principle.

In particular, Josephson tunneling measurements involving ac and dc effects comprise a powerful tool to achieve this objective, although it might happen that the intrinsically inhomogeneous nature of oxide samples will complicate the issue. There is one more obstacle to infer the cuprate order parameter symmetry directly from coherent tunneling measurements, namely, the appearance of unidirectional (stripe-like) or checkerboard (biaxial) charge-density-wave (CDW) structures in underdoped cuprates where pseudogaps are observed. The break-junction technique is an appropriate tool for this purpose.

To distinguish between indicated possibilities, various investigation techniques are needed. In particular, Josephson tunneling measurements involving ac and dc effects comprise a powerful tool to achieve this objective, although it might happen that the intrinsically inhomogeneous nature of oxide samples will complicate the issue. There is one more obstacle to infer the cuprate order parameter symmetry directly from coherent tunneling measurements, namely, the appearance of unidirectional (stripe-like) or checkerboard (biaxial) charge-density-wave (CDW) structures in underdoped cuprates where pseudogaps are observed. The break-junction technique is an appropriate tool for this purpose.
conducting families of pnictides and chalcogenides, where spin density waves (SDWs) and, possibly, also CDWs were found along with superconductivity. The microscopic origin of CDWs in cuprates is most probably the electron-phonon one (i.e. the electron spectrum of the material is gapped as a consequence of Peierls instability), although our basic phenomenological equations are similar for partial excitonic insulators. The latter state can also be realized in systems with a nested Fermi surface (FS).

In this paper, we calculated dc Josephson currents, $I_c$, between two $d$-wave (or extended $s$-wave) superconductors or one $d$-wave (extended $s$-wave) superconductor and its conventional isotropic counterpart suggesting that the CDW gapping distorts the Fermi surfaces (FS) of the high-$T_c$ electrodes. All coherent effects are regarded to be due to the Cooper pairing, so that the more exotic cases of the CDW phase-dependent tunnel currents (interesting per se!) are neglected. We assume a two-dimensional FS with CDW-gapped nested sections in accordance with the microscopic theory and observations. The results obtained show that the interference between CDWs and superconductivity can substantially alter the angle and temperature, $T$, dependences of the current $I_c$, not to talk about the amplitude of the current, which should be substantially suppressed by the dielectric gapping. In particular, the CDW sectors on the FS hot spots should lead to the non-monotonic character of the $I_c$ dependences on the angle between the crystal-lattice axes and the normal to the tunnel junction plane. Thus, Josephson current measurements probing superconducting properties may also reveal the partial CDW insulating background.

II. SOME ESSENTIAL PECULIARITIES OF CUPRATES

As is well known, the coherent properties of a collective state with Cooper pairing can be revealed by measuring the dc or ac Josephson tunnel currents between two superconducting electrodes, because the currents depend on the phase difference between superconducting order parameters in them. It is no wonder that manifestations of coherent pair tunneling are more complex for superconductors with anisotropic order parameters than for those with an isotropic energy gap. In particular, it is true for $d$-wave superconductors, where the order parameter changes its sign on the Fermi surface (FS), $^5,20,40,60,63,137,138$ As was indicated above, high-$T_c$ oxides are usually considered as $d_{x^2-y^2}$ materials. Since cuprates are considered here as main objects of study, the $d_{x^2-y^2}$-scenario will be considered as the basic one.

In addition to the unconventional, nonisotropic order parameter symmetry, high-$T_c$ oxides reveal another important peculiarity. Namely, the so-called pseudogap is observed both below and above $T_c$. Pseudogapping manifests itself in resistive, magnetic, optical, photoemission (ARPES), and tunnel (STM and break-junction) measurements as a depletion in the electron density of states, in analogy to what is observed in quasi-one-dimensional compounds above the mean-field phase-transition temperature, $^{149,150}$ Despite large theoretical and experimental efforts, the pseudogap nature still remains unknown. $^{76,79,80,89,90,121,128,143,151-167}$ Some researchers associate them with precursor order parameter fluctuations, which might be of either a superconducting or some other competing (CDWs, SDWs, etc.) origin. Another viewpoint consists in relating pseudogaps to those competing orderings, but treating them, on the equal footing with superconductivity, as well-developed states that can be made allowable for in the mean field approximation, fluctuation effects being non-crucial. We believe that the available observations support the latter viewpoint (see, e.g., recent experimental evidences of CDW formation in various cuprates, $^{88,92,116,148,168-175}$) Although underdoped cuprates are antiferromagnetic insulators, the CDW seems to be a more suitable candidate responsible for the pseudogap phenomenon. $^{76,85-87,89}$ Direct evidence that the CDW is a superconductivity destructor was obtained recently for $YBa_2Cu_3O_{7-\delta}$ by the X-ray diffraction, $^{173,175}$ for $c$-axis $Bi_{2+\delta}Sr_{2-\delta}CuO_{6+\delta}$ mesas by the intrinsic tunneling, $^{177}$ and for $Bi_2Sr_2CaCu_2O_{8+\delta}$ by the ARPES methods. However, a skepticism concerning the CDW competition with Cooper pairing still remains. Namely, the coexistence of two phenomena is qualified as a simple “intertwining”. $^{179}$ Nevertheless, the type of dominant instability competing with superconductivity in cuprates is not known with certainty. For instance, neutron diffraction studies of a number of various high-$T_c$ oxides revealed a nonhomogeneous magnetic ordering (usually associated with SDWs) in the pseudogap state. $^{180,181}$ However, whatever the nature of the pseudogap, the latter competes with Cooper pairing in underdoped and even overdoped high-$T_c$ oxide samples. $^{76,80,85-89,91,92,122,130,131,148,182-184}$ As for the mechanism of Cooper pairing per se in unconventional superconductors, it is also not known. The controversy concerns spin-fluctuations versus conventional phonons as a bosonic glue keeping electrons together.

III. MODEL PARAMETERS FOR CDW SUPERCONDUCTORS

Bearing in mind that the main objects to which our theory is applied are cuprates, the FS of the model CDW superconductor (CDWS) is approximated as a two-dimensional one. As the FS is gapped by both superconducting ($d$-wave BCS) and dielectric (CDW) instabilities, which additionally compete with each other for the quasiparticle states at the FS. Both Cooper and electron-phonon pairings are nonisotropic in the momen-
As a matter of fact, CDW distortions in cuprates are short-range and form random patches. The inhomogeneity of electronic properties in high-$T_c$ oxides is most probably intrinsic (not necessarily being of the pseudogap origin) and it may substantially influence observations. Nevertheless, in this paper, we restrict ourselves to the approximation where the CDWs constitute spatially homogeneous patterns.

We consider CDWs’s in the framework of a model, which is an extension of the Bilbro-McMillan one, initially developed for the CDW s-wave superconductors. In this model, the magnitude of CDW order parameter $\Sigma$ is assumed to be uniform (the s-wave symmetry) within the FS $d$-sections, each of the width $2\alpha$. To fix the position of $d$-sections on the FS, we introduce, the angular factor $f_\Sigma(\theta)$ (see Fig. 1),

$$f_\Sigma(\theta) = \begin{cases} 1, & \text{for } |\theta - \beta + k\Omega| < \alpha \ (d\text{-sections}) \cr 0, & \text{otherwise (nd\text{-sections})} \end{cases},$$

where $k$ is an integer number, and

$$\Omega = \begin{cases} \pi/2, & \text{checkboard CDWS } (N = 4) \cr \pi, & \text{unidirectional CDWS } (N = 2) \end{cases}.$$

In essence, the parameter $N$ equals the number of FS $d$-sections. Then, the actual dielectric order parameter $\Sigma$ distribution over the FS takes the factorized form

$$\bar{\Sigma}(T, \theta) = \Sigma(T)f_\Sigma(\theta).$$

Here, $\Sigma(T)$ is the conventional $T$-dependence of CDW order parameter.

In known high-$T_c$ superconductors, the lobes of superconducting order parameter are also directed along the $k_x$ and $k_y$ axes (see Fig. 1), which corresponds to the $d_{x^2-y^2}$-type of superconducting order parameter symmetry. (According to the adopted terminology, CDW sectors emerge in antinodal directions of superconducting lobes.) For definiteness, we select the direction of either of two CDW vectors (in the checkerboard geometry) or of the single one (in the unidirectional geometry)—in other words, the bisectrix of a CDW sector—as a reference one in the crystal. From the physical viewpoint, it is the direction of a basis vector in the inverse lattice; let it be the vector $k_x$ (see Fig. 1). This circumstance is connected with experimental conditions of crystal growing. Then, the $d_{x^2-y^2}$-type of superconducting order parameter symmetry corresponds to the value $\beta = 0^\circ$ of the mismatch angle between the bisectrices of CDW sector and superconducting order parameter lobe (for definiteness, positive). However, intensively discussed in the literature is, e.g., the $d_{xy}$-symmetry, when the superconducting lobes are rotated in the inverse lattice by $45^\circ$. Moreover, we suppose that the angle $\beta$ can acquire other values as well (formally, they can be arbitrary), e.g., if a superconductor is subjected to a non-uniform deformation. If those directions are different, the angle $\beta$ will be reckoned from the bisectrix of CDW sector to that of the

![FIG. 1. (Color online) Schematic diagram of the two-dimensional Fermi surface appropriate to cuprates and angular profiles of the $d$-wave superconducting, $f_\Delta(\theta)$, and dielectric, $f_\Sigma(\theta)$, order parameters. Charge-density waves (CDWs) are described by two, $Q_x$ and $Q_y$, or one, $Q_z$, CDW vectors. The corresponding CDW configuration function $f_\Sigma(\theta)$ possesses either two or one (non-tinted), respectively, sector pairs. $2\alpha$ is a CDW sector opening, and $\beta$ is a mismatch angle between superconducting lobes and CDW sectors (see other explanations in the text).](https://example.com/figure1)

CDWs are accompanied by the appearance of dielectrically gapped (dielectrized, d) FS sections. A necessary condition for that is the nesting of electron spectrum on them in a “parent” CDW metal. In cuprates, CDWs consist of a system with a four-fold ($N = 4$, the checkerboard pattern) or a two-fold ($N = 2$, the unidirectional pattern with spontaneous breaking of the crystal-lattice symmetry) symmetry. This situation is described (see Fig. 1) by the availability of two CDW vectors, $Q_x$ and $Q_y$, or only one, $Q_z$. The four-fold symmetry is often broken in various high-$T_c$ oxides revealing unidirectional CDWs or nematicity in nanoscale clusters. This phenomenon was considered as a manifestation of the pseudogap formation.
Here, $\Delta(T, \theta) = \Delta(T) f_\Delta(\theta)$. \hfill (5)

Here, $\Delta(T)$ is the $T$-dependent magnitude of superconducting order parameter and the angular factor $f_\Delta(\theta)$ is described in the momentum space by the sign-alternating expression

$$f_\Delta^s(\theta) = \cos 2(\theta - \beta) \hfill (6)$$

in the case of $d$-wave symmetry (see Fig. 1). We also intend to analyze, on the equal footing, the case of extended $s$-wave symmetry described by the angular function

$$f_\Delta^s(\theta) = |\cos 2(\theta - \beta)|, \hfill (7)$$

for which the superconducting gap profile is the same as in Fig. 1, but all four lobes have the same sign (for definiteness, let it be positive). We emphasize that neither the $f_\Delta^s(\theta)$ nor the $f_\Delta^s(\theta)$ angular profile depends on $T$.

The described quantities ($\alpha, N, \beta$) together with the zero-temperature values of order parameters for “parent” pure $d$-wave superconductor, $\Delta_0$, and CDW metal, $\Sigma_0$, constitute a full kit of parameter describing the partially CDW-gapped $d$-BCS superconductor. The number of energy-dependent parameters of the problem can be reduced by normalizing them by the parameter $\Delta_0$. Thus, we introduce the dimensionless parameter $\sigma_0 = \Sigma_0/\Delta_0$ describing the relative strength of the CDW and BCS pairings, the dimensionless temperature $t = T/\Delta_0$, and the dimensionless order parameters $\sigma(t) = \Sigma(T)/\Delta_0$ and $\delta(t) = \Delta(T)/\Delta_0$.

In what follows, it is convenient to introduce the notation $S_{CDW,N}^{\text{sym}}$ for a partially gapped CDW superconductor, which reflects a certain symmetry “sym” of the superconducting order parameter (see below) with the mismatch angle $\beta$ between the superconducting lobes and CDW sectors, as well as the checkerboard ($N = 4$) or unidirectional ($N = 2$) CDW configuration. The special case of $d$-wave symmetry with $\beta = 0^\circ$, as for cuprates, will be denoted in the conventional manner, $d_{\beta=0^\circ} = d_{x^2-y^2}$. For the case $d_{\beta=45^\circ}$, which we also intend to analyze, the corresponding notation is $d_{xy}$. All intermediate $\beta$ values might be possible only in the case of internal deformations, when the crystal symmetry inherent to cuprates is broken; they will not be analyzed below. As was indicated in the Introduction, we shall also consider the cases of extended $s$-wave symmetry for the superconducting order parameter, for which we shall use the notations $s_{x^2-y^2}^{\text{ext}}$ and $s_{xy}^{\text{ext}}$. We also introduce the notations $S_{\text{BCS}}^d$ for “pure” $s$- and $d$-wave superconductors, respectively.

Thus, the mixed-state CDW $d$-wave superconductor demonstrates neither pure $d$-wave nor pure $s$-wave angular behavior. This fact was indicated, e.g., while analyzing ARPES spectra of Bi$_2$Sr$_2$CuO$_{6+\delta}$.

Of course, any admixture of Cooper pairing with a symmetry different from $d_{x^2-y^2}^{\text{one}}$ may alter the results. Moreover, the superconducting order parameter symmetry might be doping-dependent. Other possibilities for predominantly $d$-wave superconductivity coexisting with CDWs lie somewhere between those pure $s$- and $d$-extremes.
IV. TUNNEL CURRENT. THEORY

A. General issues

We would like to point out that, owing to the quasi-two-dimensional character of the FS for high-$T_c$ oxides, we consider the simplest geometry of the tunnel junction between two CDWS’s. Namely, their c-axes are assumed to be parallel to each other and to the junction plane.

The dc Josephson critical current through a tunnel junction between two superconductors, whatever their order parameter symmetry, in the tunnel Hamiltonian approximation is given by the general equation\textsuperscript{20,134–136}

$$I_c(T) = 4eT \sum_{pq} |\tilde{T}_{pq}|^2 \sum_{\omega_n} F^+(p;\omega_n)F(q;\omega_n), \quad (9)$$

Here, $\tilde{T}_{pq}$ are the matrix elements of tunnel Hamiltonian; they correspond to various combinations of FS sections for superconductors taken on different sides of tunnel junction; $p$ and $q$ are the transferred momenta; $e > 0$ is the elementary electrical charge, and $F(p;\omega_n)$ and $F(q;\omega_n)$ are Gor’kov Green’s functions for superconductors to the left and to the right, respectively, of the tunnel barrier (hereafter, all primed quantities will be associated with the right hand side electrode). The internal summation is carried out over the discrete fermionic “frequencies” $\omega_n = (2n + 1)\pi T$, $n = 0, \pm 1, \pm 2, \ldots$. The external summation in Eq. (9) for the Josephson tunnel current takes into account both the anisotropy of electron spectrum $\xi(p)$ in a superconductor in the manner suggested long time ago for all kinds of anisotropic superconductors,\textsuperscript{212} the directionality of tunneling,\textsuperscript{44–51} and the dielectric electron-hole (CDW) gapping of the nested FS sections (if any).\textsuperscript{133} Let us assume for definiteness that $F(p;\omega_n) \equiv F_{\text{CDWS}}(p;\omega_n)$ corresponds to the high-$T_c$ oxide superconductor (assumed to be CDW-gapped) with a $d$-wave or extended $s$-wave order parameter. At the same time, $F(q;\omega_n)$ may correspond either to the identical high-$T_c$ oxide ($F'(q;\omega_n) \equiv F_{\text{CDWS}}(q;\omega_n)$) or an $s$-wave isotope superconductor of the original BCS model ($F'(q;\omega_n) \equiv F_{\text{BCS}}(q;\omega_n)$) with the order parameter $\Delta_{\text{BCS}}(T)$. Thus, we restrict the consideration to two representative cases: (i) the symmetric junction $S_{\text{CDWS}}^\text{sym} - I - S_{\text{CDWS}}^\text{sym}$ involving identical high-$T_c$ superconductors separated by an insulator interlayer 1 (this case will be denoted as sj-S$_{\text{CDWS}}^\text{sym}$); and (ii) the nonsymmetric $S_{\text{CDWS}}^\text{sym} - I - S_{\text{BCS}}^\text{sym}$ one (nj-S$_{\text{CDWS}}^\text{sym}$). Figure 2 illustrates both those cases for the checkerboard CDW scenario ($N = 4$) and the order parameter mismatch angle $\beta = 0^\circ$.

We consider the gap rose of the CDWS to the left from the junction plane to be oriented at the angle $\gamma$ with respect to the normal $n$ to the plane. The orientation direction of the whole CDWS is determined by the direction of the bisectrix of the positive superconducting order parameter lobe in the parent BCS superconductor (see Section III and Appendix A). The actual order parameter profiles are governed by the crystal lattice geometry. At the same time, the junction plane is created artificially and, generally speaking, the normal $n$ to it may not coincide with any crystal axis. In the symmetric junction geometry, the same superconductor is to the right from the junction, but its gap rose may be oriented at a different angle, $\gamma'$, with respect to the normal. In the case of non-symmetric junction geometry, the gap rose of the right hand side superconductor (S$^\text{BCS}$) is an isotropic circle.

B. Tunnel directionality

Specifying the dc Josephson current (9), we introduce two kinds of directionality. The first one involves the factors $|v_{g.n.d} \cdot n|$ and $|v_{g.d} \cdot n|$,\textsuperscript{58,63,213} where $v_{g.n.d} = \nabla \xi_{nd}$ and $v_{g.d} = \nabla \xi_d$ are the normal-state quasiparticle group velocities for proper FS sections. Those factors can be considered as proportional to the number of electron attempts to penetrate through the barrier.\textsuperscript{137} They were introduced decades ago in the framework of general problem dealing with tunneling in heterostructures.\textsuperscript{214–216} In the framework of the phenomenological approach adopted here (cf. approaches in Refs. 40, 60, 64, 137, 138, and 217), this multiplier can be factorized into $\cos \theta$, where $\theta$ is the angle at which the pair/quasiparticle transmits through the barrier, and an angle-independent coefficient, which can be in the usual way incorporated into the junction normal-state resistance $R_N$ (see below).

In addition, in agreement with previous studies,\textsuperscript{44,45,47,48,50,218} the tunnel matrix elements $\tilde{T}_{pq}$ in Eq. (9) should also make allowance for the tunnel directionality (the angle-dependent probability of penetration through the barrier).\textsuperscript{62,63,96,213} The problem is rather difficult. Even if the barrier were uniformly rectangular over the whole junction plane and the WKB approximation were sufficient for calculations, the
situation would not be simple.\textsuperscript{62} Really, in this case, for a particle traversing the barrier at an angle $\theta$, the barrier penetration coefficient would be proportional to $\exp(-h_0d)$, where $h_0$ is the effective barrier height for the particle (the difference between the particle and barrier top energies), $d = L/\cos \theta$ is the relevant tunnel path, and $L$ is the junction thickness. We do not know the actual $\theta$ dependences for realistic junctions from microscopic considerations. Therefore, similarly to what was proposed in Ref. 44, we simulate the barrier-associated directionality by the phenomenological function

$$w(\theta) = \exp \left[-\ln 2 \times \left(\frac{\tan \theta}{\tan \theta_0}\right)^2\right] \quad (10)$$

so that the cone opening of effective tunnel angles equals to $2\theta_0$ (this parameter depends on $L$) (see Fig. 2). The barrier transparency is normalized by the maximum value obtained for the tunneling normally to the junction plane and included into the junction resistance $R_N$; hence, $w(\theta = 0) = 1$. The multiplier $\ln 2$ in Eq. (10) was selected to provide $w(\theta = \theta_0) = \frac{1}{2}$.

C. Green’s functions

In accordance with the previous treatments of partially gapped CDW s-wave superconductors\textsuperscript{85–87,93,133,205,206,219–225} and their generalization to their d-wave counterparts,\textsuperscript{76,89,90,95,207,226} and in line with the basic theoretical framework for unconventional superconductors\textsuperscript{64,227} the anomalous Gor’kov Green’s functions for d- or extended s-wave superconductors are assumed to be different for angular sectors with coexisting CDWs and superconductivity (d sections of the FS) and the “purely superconducting” rest of the FS (nd sections)

$$F_{\text{CDWS,nd}}(p;\omega_n) = \frac{\Delta(T, \theta)}{\omega_n^2 + \Delta^2(T, \theta) + \xi_{\text{nd}}^2(p)}, \quad (11)$$

$$F_{\text{CDWS,d}}(p;\omega_n) = \frac{\Delta(T, \theta)}{\omega_n^2 + D^2(T, \theta) + \xi_{\text{d}}^2(p)}. \quad (12)$$

Here, the angle $\theta$ is reckoned from the tilt angle $\gamma$ ($\gamma'$) in the case of left (right) hand side electrode. The quasiparticle spectra $\xi_{\text{d}}(p)$ and $\xi_{\text{nd}}(p)$ correspond to “hot” and “cold” spots of the cuprate FS, respectively (see, e.g., Refs. 91, 111, 119, 130, 148, 183, 228, and 229). It is evident that Eq. (11) is a particular case of expression (12), since, owing to formula (8), the gap $\Delta(T, \theta)$ on the nd FS section equals $\Delta(T, \theta)$. The difference between Green’s functions for d- or extended s-wave superconductors consists in the proper choice of the order parameter angular profile $f_\Delta(\theta)$ (see Eqs. (6) and (7)). The Gor’kov Green’s function for the conventional s-wave superconductor has the standard form

$$F_{\text{BCS}}(p;\omega_n) = \frac{\Delta_{\text{BCS}}(T)}{\omega_n^2 + \Delta_{\text{BCS}}^2(T) + \xi_{\text{BCS}}^2(p)}. \quad (13)$$

It is also a particular case of Eq. (12), in which, besides the absence of dielectric gapping, the dependence on the angle $\theta$ is also absent. The d-wave, $\Delta(T)$, and s-wave, $\Sigma(T)$, gap functions are calculated self-consistently on the basis of BCS-like electron-electron and electron-hole attraction characterized by the strengths $\Delta_0$ and $\Sigma_0$, respectively.\textsuperscript{76,89,90,95} As was indicated in Section III, the quantities $\Delta_0$ and $\Sigma_0$ are zero-$T$ values of the relevant energy gaps in the absence of competing interaction. In particular, at $\Delta = 0$, the dependence $\Delta(T)$ is given by the s-wave M"uhlschlegel function.\textsuperscript{1,231} On the other hand, at $\Sigma = 0$, the dependence $\Delta(T)$ is determined by the weak-coupling equation for the d-wave superconductor.\textsuperscript{231} The self-consistent dependences $\Delta(T)$ and $\Sigma(T)$ for extended s-wave superconductors are identical to those for d-wave ones.

D. dc Josephson current

Substituting Eqs. (11), (12), and (13) into Eq. (9), carrying out standard transformations,\textsuperscript{134,135} assuming the coherent character of tunneling,\textsuperscript{37,44,62} as opposed to the non-coherent approximation\textsuperscript{212,213} valid for isotropic superconductors, and making some simplifications, we arrive at the following formula for the dc Josephson current across the tunnel junction:

$$I_c(T, \gamma, \gamma') = \frac{1}{2eR_N} \times \frac{1}{\pi} \int_{-\pi/2}^{\pi/2} d\theta \cos \theta \ W(\theta) \ P(T, \theta, \gamma, \gamma'), \quad (14)$$

where\textsuperscript{133,212}

$$P(T, \theta, \gamma, \gamma') = \frac{\max\{\bar{D},\bar{D}'\}}{\min\{\bar{D},\bar{D}'\}} \ \int_{\min\{\bar{D},\bar{D}'\}}^{\max\{\bar{D},\bar{D}'\}} \frac{dx \tanh \frac{\pi}{2}\sqrt{D^2 - x^2}}{\sqrt{x^2 - \bar{D}^2}}. \quad (15)$$

Here, for brevity, we indicated the dependences $\bar{D}(T, \theta - \gamma)$, $\bar{D}'(T, \theta - \gamma)$, $\bar{D}(T, \theta - \gamma)$, and $\bar{D}'(T, \theta - \gamma')$ without their arguments. Formula (14) is applicable for both the symmetric (with an accuracy to the electrode orientation) and non-symmetric junctions. The parameter $R_N$ is the normal-state resistance of the tunnel junction determined by $|T_{\text{pq}}|^2$ without the factorized multiplier $W(\theta)$. Integration over the angle variable $\theta$ is carried out within the interval $-\frac{\pi}{2} \leq \theta \leq \frac{\pi}{2}$, i.e. over the “FS hemicircle” turned towards the junction plane. As was also indicated above, we put $W(\theta) = \cos^2 \theta$ in subsequent calculations. Formula (14) was obtained in the weak-coupling approximation,\textsuperscript{232} i.e. the reverse influence of the energy gaps on the initial FS was neglected.

At $W(\theta) \equiv 1$ (the tunneling directionality associated with the $\theta$-dependent barrier transmittance is ne-
neglected), putting \( f_s^{(t)} = 1 \) (actually, it is a substitution of an isotropic \( s \)-superconductor for the \( d \)-wave or extended \( s \)-ones) and \( f_s^{(t)} = 0 \) (the absence of CDW-gapping), as well as substituting \( \cos \theta \) by 1 (the absence of tunnel directionality). Eq. (14) expectedly reproduces the basic Ambegaokar–Baratoff result for tunneling between \( s \)-wave superconductors.\(^{134-136,239,232}\) On the other hand, if the directionality and dielectric gapping are excluded but \( f_s \) and \( f_D \) are retained we return to the Sigrist-Rice model.\(^{59}\) Note, that we restricted ourselves to the classical tunnel junction\(^{134,135,232}\) being a strong-barrier limit of the more general model.\(^{234}\) It means that Andreev-Saint-James-reflection processes\(^{40,235-237}\) were disregarded.

In this paper, we do not consider the \( T \)-dependences of dc Josephson current. It will be done in a separate paper. Therefore, all further calculations will be carried out for the zero temperature, \( T = 0 \). In this case, formula (15) can be expressed in terms of complete elliptic functions,\(^{134,238}\)

\[
P(\theta, \gamma, \gamma') = \frac{\bar{\Delta} \bar{\Delta}'}{\max \{D, D'\}} \times K \left( 1 - \frac{\min \{D, D'\}}{\max \{D, D'\}} \right)^2.
\]

(16)

Here again, the reduced notations should be understood as follows: \( \bar{\Delta} = \bar{\Delta}(T = 0, -\gamma - \gamma') \), \( \bar{\Delta}' = \bar{\Delta}'(T = 0, \theta - \gamma') \), \( D = D(T = 0, \theta - \gamma) \), and \( D' = D'(T = 0, \theta - \gamma') \). In the general case \( T \neq 0 \), integration has to be carried out numerically.

V. PRELIMINARY CALCULATIONS

A. Reference CDW superconductors: the choice of parameters

The formulated problem does not allow the final results to be derived in an analytical form. Therefore, we must confine ourselves to numerical calculations. All issues associated with the influence of inherent CDWS parameters—the relative strength of superconducting and CDW pairing, \( \sigma_0 \), and the degree of FS dielectrization, \( \alpha \)—as well as the temperature, \( t \), on the dc Josephson current will be analyzed in a separate paper. Here, we consider only various orientation dependences, in order to check whether they can be useful to establish the type of superconducting pairing symmetry and CDW configuration in high-\( T_c \) superconductors. We confine the consideration to the case \( t = 0 \). Specific values of the problem parameters indicated above were estimated on the basis of the available experimental data.

First of all, these are the parameters \( \sigma_0 \) and \( \alpha \) for the “reference” CDWS. According to the ARPES measurements for underdoped \( \text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x} \) (Refs. 80, 111, 178, 239, and 240) and \( \text{(Bi,Pb)}_2\text{(Sr,La)}_2\text{CuO}_{6+y} \) (Refs. 80, 157, and 184), we may estimate the value of the parameter \( \alpha \) (the angular width of the nodal area affected by electron specturm dielectrization) to be about 15°. The same experiments together with STM\(^{72,141,199,241-244}\) and break-junction\(^{94,245}\) studies lead to the ratio between the critical superconducting, \( T_c \), and pseudogap, \( T_s \), temperatures of about or less than 1:3. For instance, tunnel measurements of nearly optimally doped \( \text{Bi}_2\text{Sr}_2\text{La}_x\text{CuO}_{6+y} \) \((x = 0.4)\) mesa-structures revealed \( T_s \approx 165\, K \), the onset superconducting critical temperature \( T_{c0} \approx 40\, K \) and the “true” critical temperature \( T_c \approx 30\, K \).\(^{244}\) The ratio 1:3 can be satisfactorily reproduced in the framework of our CDWS model, if we put \( \sigma_0 = 1.3 \) at \( N = 4 \) and \( \beta = 0 \), i.e. for the \( S_{CDW4}\) superconductor. More specifically, \( t_c = T_c/\Delta_0 \approx 0.23 \) and \( t_s = T_s/\Delta_0 \approx 0.74 \) so that \( t_c : t_s \approx 1 : 3.2 \). The zero-temperature values of order parameters are shown in Table I. Note that the corresponding calculated ratio between the zero-temperature order parameters \( \sigma(0) \) and \( \delta(0) \) for the \( d_{x^2-y^2} \) superconducting order parameter and the checkerboard CDWs is approximately equal to 1:9, whereas the direct measurements\(^{246}\) of relaxation dynamics of photo-excited quasiparticles in \( \text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{6+y} \) reveals \( \Delta(0) = 41\, meV \), \( \Delta(0) = 24\, meV \) so that \( \Sigma(0)/\Delta(0) \approx 1.7 \), which confirms the adequacy of the selected parameters.

This combination of problem parameters—an \( S_{CDW,N}^{sym} \) superconductor with the superconducting pairing symmetry \( \text{sym} = d_{x^2-y^2} \), the checkerboard CDW configuration \((N = 4)\), and the parameters \( \sigma_0 = 1.3 \) and \( \alpha = 15^\circ \)—is selected below as the reference one. We intend to illustrate the influence of such parameters as “sym” and \( \alpha \) on the orientation current characteristics, leaving the parameters \( \sigma_0 \) and \( \alpha \) constant. Table I also quotes the relevant parameter values for other \( S_{CDW,N}^{sym} \) possible “reference” superconducting states considered in this paper. The corresponding zero-\( T \) gap rose can be found in Appendix A. Although the considered order parameter symmetries are most likely not realized in cuprates, they might appear in other superconductors and, hence, deserve to be examined.

To detect the influence of CDW on the tunnel current, we also need a corresponding CDW-free reference object. As will be seen below, in this case the best such objects for the \( S_{CDW,N}^{sym} \) superconductor are the pure \( S_{BCS} \) ones with \( \delta_{BCS}(0) \) equal to \( \delta(0) \) of the former (one should bear in mind that, in the general case, \( \delta(0) < \delta_0 = 1 \)). We shall refer to this BCS superconductor as “BCS counterpart”. It involves no CDW sectors, and we define its orientation by the bisectrix of the positive lobe of the superconducting order parameter.

We also select Nb as an \( S_{BCS} \) superconductor. Then, the ratio between its superconducting gap\(^{247}\) and those in typical high-\( T_c \) oxides\(^{248}\) gives the value \( \delta_{S_{BCS}}(0) = 0.1 \).
The angle of effective tunneling in Eq. (10) has a high degree of uncertainty. First, let us consider the angular dependences of the normalized dc Josephson current, \( i_c(\gamma) \), in the \( \text{nj}-S^{d,2}_\text{CDW} \) junction between the reference CDW \( d \)-wave and BCS \( s \)-wave superconductors (see Section V A). \( \delta \text{BCS}(0) = 0.1 \). Positive and negative \( i_c \) values are marked by light and dark colors, respectively.

As was said above, this paper is devoted to the analysis of orientation dependencies of dc Josephson current, i.e., the dependences of \( i_c \) on the angles \( \gamma \) and \( \gamma' \) (see Fig. 2), for various kinds of electrodes in order to determine whether they can be useful in establishing the superconducting pairing symmetry and the availability of CDWs in high-\( T_c \) superconductors. For this purpose, we will confine the scope of presented material by reporting the results obtained for model \( S^{\text{sym}}_{\text{CDW}} \) CDWs’s with the common parameters \( \sigma_0 = 1.3 \) and \( \alpha = 15^\circ \). The sets of other parameters are \( \text{sym} = (d, s^{\text{ext}}), \beta = (0^\circ, 45^\circ), \) and \( N = (2, 4) \).

First, let us consider the angular dependencies describing the influence of different crystal orientations relative to each other and the junction plane. In Fig. 4(a), the dependences \( i_c(\gamma, \gamma') \) for the \( \text{sj}-S^{d,2}_\text{CDW} \) junction are depicted. The role of CDW dielectricization becomes clear if we make a comparison with the analogous dependence, but for the \( \text{sj}-S^{d}_\text{BCS} \) junction containing the electrodes of the corresponding \( S^{d}_\text{BCS} \) counterpart (Fig. 4(b), see Section V A). Note that in the latter case, both \( \gamma \) and \( \gamma' \) are reckoned from the junction-plane normal \( n \) and determine the orientation of the positive superconducting order parameter lobes (see Fig. 2). One can see that, against the background of smooth oscillations with a period of 180°, the dependence \( i_c(\gamma) \) demonstrates some distortions, which are the most appreciable at the minima and maxima.

An analogous comparison is even more spectacular and illustrative for the cases of symmetric junctions with an \( S^{d,2}_\text{CDW} \) superconductor and its \( S^{d}_\text{BCS} \) counterpart (Fig. 5). The reason is that in this case the superconduct-
equal to $180^\circ$. Now, the period of electrode orientation in such a way that its CDW sector is almost indistinguishable. However, if either of its Sd crystalline high-symmetries: four- and two-fold, respectively (see the gap configuration, checkerboard or unidirectional.

An interesting configuration may arise if a single-crystalline high-$T_c$ sample is cut at an arbitrary angle with respect to the crystal axes. Later on, both pieces are used as electrodes in the same tunnel junction. In essence, we would obtain a correlated rotation of crystals on the both junction sides. Accordingly, it means a correlated rotation of electrodes’ CDWs with the orientation mismatch angle $\Delta \gamma = \gamma - \gamma' = 0$. The results of numerical simulation of such an experiment are presented in Fig. 6 for the sj-S$^{d_{x^2-y^2}}_{\text{CDW2}}$ (panel a) and sj-S$^{d_{x^2-y^2}}_{\text{BCS}}$ (panel b) junctions. Besides the case $\Delta \gamma = 0$, the figure also exhibits the corresponding dependences for the orientation mismatch angles $\Delta \gamma = 45^\circ$, $90^\circ$, and $135^\circ$. Actually, these dependences are nothing else but the cross-sections of the corresponding surfaces $i_c(\gamma, \gamma')$—for panel a, it is the surface depicted in Fig. 4(a)—by the relevant planes $\gamma' - \gamma = \text{const.}$

One should pay attention that, if $\Delta \gamma = 0$, the sign of integrand in formula (14) is always positive, because the signs of $\Delta$ and $\Delta'$ (see the coefficient before the integral in Eq. (15)) are identical at any $\theta$. Therefore, the current is also positive for any $\gamma$, which is very similar to the case of $s^{\text{ext}}_{x^2-y^2}$-wave pairing (see below). A symmetric situation with an accuracy to the current sign is observed when the orientation mismatch angle $\Delta \gamma = 90^\circ$ because now $\Delta(\theta) = -\Delta'(\theta)$. It is also clear that dependences $i_c(\gamma)$ for $\Delta \gamma = 0$ and $90^\circ$ should differ from each other only by sign, because the dependences $D(\theta)$ and $D'(\theta)$ are identical.

A similar result is obtained for the sj-S$^{d_{x^2-y^2}}_{\text{CDW2}}$ junction (Fig. 4(b)). But now, the dependences $D(\theta)$ and $D'(\theta)$ have the two-fold rotational symmetry and are identical only when $\Delta \gamma = 0$. Therefore, the dependence $i_c(\gamma)$ for $\Delta \gamma = 0$ is not a specular reflection of that for $\Delta \gamma = 90^\circ$.

The considered feature of sign preservation by the current within definite vicinities of mismatch angles $\Delta \gamma = 0$ and $90^\circ$ is possible only due to the tunnel directionality. All other angles lead to the intermediate situations of variable sign. To get a better idea of them, the latter (unidirectional) case is illustrated in Appendix C in more

![Diagram](attachment:image.png)
FIG. 6. (Color online) Dependences $i_c(\gamma)$ for the (a) sj-$S^d_{CDW4}$ and (b) sj-$S^d_{CDW2}$ junctions for correlated rotations of CDWs in electrodes at various fixed differences $\gamma' - \gamma$.

B. Symmetric junctions. Superconducting pairing symmetry

An interesting question consists in checking whether we can use the orientation dependences of the stationary Josephson current to discern the pairing symmetry of high-$T_c$ superconductors in the presence of CDWs. In Fig. 7, the dependences $i_c(\gamma)$ are depicted for sj-$S^\text{sym}_{CDW4}$ junctions with various values of parameter “sym”. One can see that the curves are qualitatively different and, therefore, may provide the required information.

At the same time, we see again that, in general, the CDW-induced peculiarities in the orientation dependences $i_c(\theta)$ are rather weak for the selected reference parameter set and can be easily overlooked against the large background superconducting behavior. This situation is illustrated in Fig. 8 for the sj-$S^d_{CDW2}$ junction. In particular, panel b demonstrates that the discussed peculiarities, interesting per se, are observable only at certain misorientations between the electrodes, being effectively “absorbed” at other angles.

C. Non-symmetric junctions.

Non-symmetric Josephson junctions (nj-$S^\text{sym}_{CDW_N}$), where one of electrode is a pure $S^\text{sym}_{BCS}$ superconductor, is described by a “shorter” list of parameters. In particular, the $S^\text{sym}_{BCS}$ is characterized by a single parameter, $\delta_{BCS}$, and is isotropic (the orientation angle $\gamma'$ loses its sense). As a result, the corresponding orientation dependences $i_c(\gamma)$ are not so diversified as in the symmetric case. Nevertheless, nj-$S^\text{sym}_{CDW_N}$ junctions are rather important, because they correspond to the STM geometry with a superconducting tip, which can be practically realized.

Generally speaking, it is not strange that $i_c(\gamma)$ dependences should be qualitatively similar to those obtained in the symmetric setup at fixed orientations of the r.h.s. electrode. Therefore, we confine the subject of this Section to the influence of the possible superconducting pairing symmetries in the CDWS electrode on the overall angle dependences. The results of relevant calculations are depicted in Fig. 9 for the cases of checkerboard (panel a) and unidirectional (panel b) CDW configurations. The calculations were carried out for the reference set of parameters. One can see, that the character of dependences changes drastically from one pairing symmetry to another, and the distinction is more pronounced in the case of unidirectional CDWs.
VII. CONCLUSIONS

Our calculations showed that CDWs induced by the electron-hole pairing and appropriate to high-$T_c$ cuprates can be probed and studied by means of the coherent superconducting dc Josephson tunneling. The interplay between CDW manifestations, tunnel directionality, and possible unconventional symmetry of the superconducting order parameter may lead to an involved behavior with several superimposed periods in the angular dependences. Symmetric junctions (break-junctions, mesas) are preferable in comparison with non-symmetric ones (STM) in revealing CDW effects.

The results obtained confirm that the dc Josephson current is always suppressed by the electron-hole (dielectric) CDW pairing, which, in agreement with the totality of experimental data, is assumed here to compete with its superconducting electron-electron (Cooper) counterpart. We emphasize that, as concerns the quasiparticle current, the interpretation of the results may be much more ambiguous. In particular, the states in the nodal region of the FS in $d$-wave superconductors are also engaged into CDW gapping\cite{76,89,90,95,207,220,249} so that the tunnel spectroscopy (or ARPES) feels the overall energy gaps being larger than their superconducting constituent. We demonstrated that the emerging CDWs distort the dependence of the critical Josephson $I_c$ on the angle $\gamma$ between a certain crystal axis and the normal $\bf n$ to the junction plane, whatever the symmetry of superconducting order parameter is. At the same time, if an $s$-wave contribution to the actual order parameter in a cuprate sample is dominant up to the complete disappearance of the $d$-wave component, the $I_c(\gamma)$ dependences for junctions involving CDW superconductors are no longer constant as in the CDW-free case. This prediction can be verified for CDW superconductors with $a$ fortiori $s$-wave order parameters (such materials are quite numerous\cite{76,85–87,89,90}).

In this paper, our approach was purely theoretical. We did not discuss unavoidable experimental difficulties if one tries to fabricate Josephson junctions suitable to check the results obtained here. We are fully aware that the emerging problems can be solved on the basis of already accumulated knowledge concerning the nature of grain boundaries in high-$T_c$ oxides\cite{17–20,23,250–256}.
Note that required junctions can be created at random in an uncontrollable fashion using the break-junction technique. This method allows to comparatively easily detect CDW (pseudogap) influence on the tilt-angle dependences.

To summarize, measurements of the Josephson current between an ordinary superconductor and a d-wave or extended s-wave one or between two unconventional superconductors (first of all, high-$T_c$ oxides) would be useful to detect a possible CDW influence on the electron spectrum of the latter. Similar studies of iron-based superconductors with doping-dependent spin density waves (SDWs) would also be of benefit (see, e.g., recent reviews 105 and 108), since CDW and SDW superconductors have certain similar properties.\textsuperscript{85–87}

VIII. ACKNOWLEDGEMENTS

The work was partially supported by the Project N 8 of the 2012-2014 Scientific Cooperation Agreement between Poland and Ukraine. The authors are grateful to Sergei Borisenko (Dresden), Alexander Kordyuk (Kyiv), and Sergei Ryabchenko (Kyiv) for useful discussions of the interplay between charge density waves and superconductivity.

Appendix A: Gap roses

Due to a competitive interaction between Cooper and electron-hole pairings, both leading to the electron spectrum gapping, the actual values of relevant order parameters, \( \Delta(T) \) and \( \Sigma(T) \) are smaller than the corresponding “parent” values \( \Delta_0 \) and \( \Sigma_0 \) (see Section III). Besides, the dielectric (CDW) order parameter “occupies” only some sections (d-sections) of the FS. As a result, a rather involved allocation of the combined energy gap \( \bar{D}(T, \theta) \) arises on the FS (see Eq. (8)). For the calculation of dc Josephson current (see Eqs. (14) and (15)), two quantities are important: \( \bar{D}(T, \theta) \) (the so-called “gap rose”) and \( \bar{\Delta}(T, \theta) \). They can be extracted, e.g., from the ARPES measurements. The overall angular patterns differ substantially from the pure d-wave dependence \( \cos \theta \).\textsuperscript{89,90,207,257}

Both \( \bar{D}(T, \theta) \) and \( \bar{\Delta}(T, \theta) \) are anisotropic in the momentum space. Therefore, tunnel directionality will inevitably result in the dependence of the stationary Josephson current \( i_s \) on the orientation of both CDWS crystal axes with respect to the junction plane, the angles \( \gamma \) and \( \gamma' \) (see Fig. 2). In this paper, we analyze the dependences \( i_s(\gamma, \gamma') \) for the cases when the electrodes are \( S_{CDW1}^{d_{x^2+y^2}} \), \( S_{CDW2}^{d_{x^2+y^2}} \), \( S_{CDW4}^{d_{x^2+y^2}} \), and \( S_{CDW2}^{d_{x^2+y^2}} \) superconductors. We restrict ourselves to the case \( T = 0 \) and make specific calculations for a CDW with the parameters \( \sigma_0 = 1.3 \) and \( \theta_0 = 15^\circ \). The corresponding \( \bar{\Delta}(T, \theta) \) and \( \bar{D}(T, \theta) \) profiles over the two-dimensional FS are exhibited in Figs. 10 and 11. On the nd-sections, both profiles coincide.

Note that, in all cases, the influence of FS dielectrization on superconductivity is revealed as a decrease of the actual \( \delta(T = 0) \) value—the amplitude of superconducting order parameter lobes—with respect to the “parent” one, \( \delta_0(T = 0) = 1 \). The figures demonstrate that this effect is stronger if the dielectrized FS fraction is larger (the checkerboard CDW configuration, \( N = 4 \), versus the unidirectional one, \( N = 2 \)). At the same time, this influence is more pronounced in the case of \( d_{x^2-y^2} \)-wave superconducting order parameter symmetry, inherent to cuprates, because in the \( d_{x^2-y^2} \)-case, the d-sections are located around the nodal points of the superconducting order parameter, whereas the superconducting order parameter lobes are the “most developed” on the nd-sections, so that their interplay is minimal.

The vector in each panel defines the orientation of corresponding CDWS, so that the angles \( \gamma \) and \( \gamma' \) in Eq. (14) are the angles between the vector \( \mathbf{n} \) normal to the junction plane (see Fig. 2) and the indicated vectors on the l.h.s. and r.h.s of the junction, respectively.

In the case of s-extended symmetry of superconducting order parameter—i.e. if the electrodes are \( S_{CDW4}^{d_{x^2+y^2}}, S_{CDW2}^{d_{x^2+y^2}}, S_{CDW4}^{d_{x^2+y^2}} \), and \( S_{CDW2}^{d_{x^2+y^2}} \) CDWS’s—the gap roses remain the same, but all \( \Delta \) lobes have the same sign (we took it positive, for definiteness).

Appendix B: Analysis of directionality

This section includes some illustrative sets (see Fig. 12) of \( i_s(\gamma, \theta_0) \) dependences calculated, in addition to that shown in Section V B (Fig. 3), for the \( s_{ij}S_{CDW1}^{d_{x^2+y^2}} \) (panel a), \( sjS_{CDW1}^{d_{x^2+y^2}} \) (panel b), and \( njiS_{CDW1}^{d_{x^2+y^2}} \) (panel c) junction setups with the same reference set of parameters (see Section V A). One can see that, for all those cases, the value of effective tunneling angle \( \theta_0 = 10^\circ \) in formula (10) is the best choice for the demonstration of the influence of CDW on the orientation dependences of dc Josephson current \( i_c(\gamma) \). The corresponding choice is marked as the bold curve. Of course, it is not known which \( \theta_0 \) is inherent to any created junction. However, one might expect that the interlayer variation readily realized, e.g., in break-junctions, would produce a broad spectra of \( \theta_0 \).

Appendix C

In this Appendix, we plotted the dependences \( i_s(\gamma) \) for the \( sjS_{CDW1}^{d_{x^2+y^2}} \) junction described in Section VI A (Fig. 6(b)) with the varying orientation \( \gamma' \) of the r.h.s. electrode, but in a more detailed representation (see Fig. 13). The curves corresponding to the characteristic cases \( \gamma' = 0 \) and 90\(^\circ\) are shown in bold. In essence, this
